Yu's Elite Education

Last week recap

- ▶ Linked lists
 - ▶ Advantages/Disadvantages over arrays
 - ▶ Singly vs. doubly-linked
- ▶ Queues
 - ▶ FIFO
- ▶ Stacks
 - ▶ FILO

Homework: Find list median

Associative arrays

- ▶ Regular array/list: maps nonnegative integer keys onto values, e.g. `states[3] = 'NJ'`
- ▶ Associative arrays: map any key onto values, e.g. `capitals['NJ'] = 'Trenton'`
 - ▶ Want to be able to add, delete, and modify each key/value pairing
 - ▶ Called dictionaries in Python
 - ▶ Can also be used without values (sets)

Associative arrays

- ▶ How to implement associative arrays?
- ▶ Can just store a list of key-value pairs

Index	Key	Value
0	NJ	Trenton
1	NY	Albany
2	PA	Harrisburg

- ▶ Big-O for add, delete, find, modify?
 - ▶ Add: $O(1)$
 - ▶ Find, modify, delete: $O(N)$
 - ▶ Memory: $O(N)$

Speeding up find and delete

- ▶ Goal: Find items in $O(1)$ time, without increasing memory requirement too much
- ▶ Strategy: Convert every key to a nonnegative index, then use a regular array
- ▶ Example:
 - ▶ Initialize capitals to be empty length-10 array
 - ▶ When adding 'NJ', plug 'NJ' into a function $f('NJ') = 4$
 - ▶ Store 'Trenton' in capitals[4]

Hash function

- ▶ The function converting keys into indices is called the *hash* function
- ▶ Input: Keys (may be any type)
- ▶ Output: Nonnegative index where we should store the value of that key
- ▶ **Ideally, we want all keys to be mapped to different indices**

Example: Website logins

- ▶ Four users sign up for website:
 - ▶ Praneel, Areeq, Jimmy, Allen
 - ▶ $f(\text{Praneel}) = 5$, $f(\text{Areeq}) = 2$, $f(\text{Jimmy}) = 0$, $f(\text{Allen}) = 3$
- ▶ Store their passwords in hash table

Big-O for hash table

- ▶ If hash function successfully maps all keys to different indices, then:
 - ▶ Add: $O(1)$
 - ▶ Find: $O(1)$
 - ▶ Modify: $O(1)$
 - ▶ Delete: $O(1)$
- ▶ What's the catch??
- ▶ Will need to use extra memory: for good hash function, memory should still be $O(N)$

Designing a hash function

- ▶ When picking a hash function f , we want it to distribute keys uniformly over the array

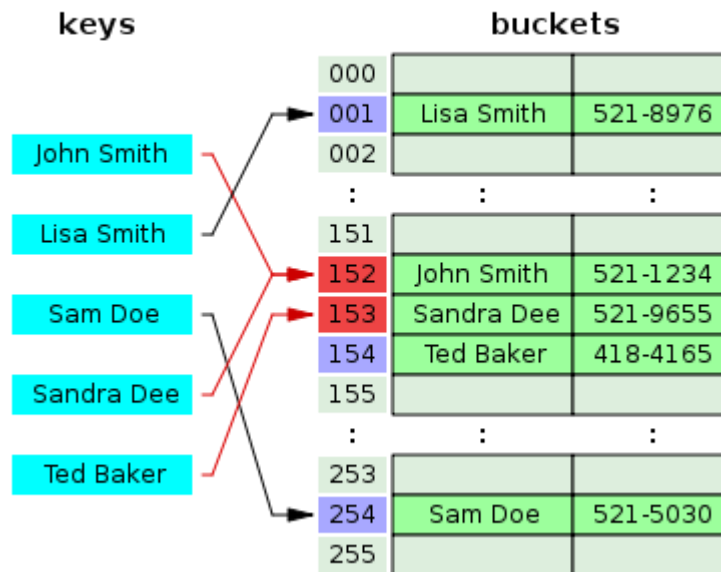

Collisions

- ▶ As long as our array is smaller than the total number of possible keys (e.g. all possible usernames), there will always be *collisions*
 - ▶ Collision occurs when $f(\text{key1}) = f(\text{key2})$
- ▶ Collisions more likely to happen if:
 - ▶ Array is not big enough
 - ▶ Hash function isn't uniform
- ▶ What do we do when we go to add a key/value but another key is already there?

Dealing with collisions: Open Addressing

- ▶ If there is a key/value in your spot, just use the next open spot

Dealing with collisions: Chaining

- ▶ Chaining: Each array bucket contains a list of all key/values mapped to that bucket
- ▶ Usually used a linked list

Dealing with collisions

- ▶ Open addressing easiest when keys are small and have at least twice as many memory slots as keys
- ▶ Otherwise, chaining better:
 - ▶ Only stores pointers in array
 - ▶ Can have more keys than memory slots
 - ▶ Can handle variable-sized data

Python hashing example

Olympiad Problem

► Censoring:

Hashes in cryptography

- ▶ Often we want to prove that two pieces of data match, *without* looking at them
- ▶ Very common example: passwords
 - ▶ Websites/computers want to check if the password you're entering now matches the one you signed up with
 - ▶ BUT don't want to just store a copy of password, otherwise a hacker/insider could mass-copy passwords out of the database

Hashes in cryptography

- ▶ Solution: only store a *hash* of the password
- ▶ A good hash function will rarely have collisions - so if password hashes match, passwords almost certainly match!
- ▶ Cryptographic hashes also designed to make sure they are hard to reverse (hard to get from hash to password)

Attacking a hash

- ▶ Let's say we lost our password and only have the hash (or we're doing something evil)
- ▶ How can we get password just given the hash?
- ▶ Could just try every possible password, and store all hashes
 - ▶ This will take a looong time, but we only ever have to do it once
 - ▶ Then we can use this table many times for this hash function
 - ▶ Called "Rainbow Tables"

Python hash attack example

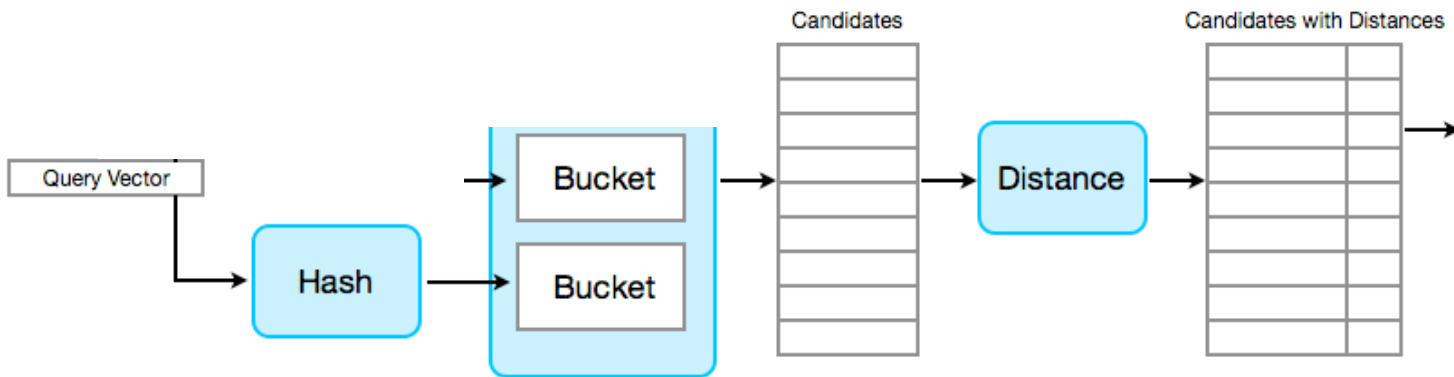

“Opposite” kind of hashing

- ▶ For hash tables, we want to avoid collisions
- ▶ When might we *want* collisions?
- ▶ Main use: detecting nearest neighbors
 - ▶ If we map similar values to the same bucket, hashing will find close neighbors
- ▶ Called *locality-sensitive hashing*

Examples of LSH

- ▶ Finding near-duplicates
 - ▶ Detecting plagiarism
 - ▶ Finding other sizes of image
 - ▶ Avoid duplicate search results
- ▶ Recommender systems
 - ▶ Find similar customers, see what they bought
 - ▶ Find similar movies to your favorites

Finding closest neighbors with LSH

LSH for detecting breaking news on Twitter

Incoming Tweet	Closest previous Tweet	Similarity Score

Assignment: Anagrams

- ▶ Given a dictionary
<http://www.codeabbey.com/data/words.txt>
divide it into groups of anagrams
- ▶ Example: tea, asleep, plus, ate, please
 - ▶ [tea, ate], [asleep, please], [plus]
